Wound bed preparation:
A novel approach using HydroTherapy

Abstract

Wounds that fail to heal quickly are often encountered by community nursing staff. An important step in assisting these chronic or stalled wounds progress through healing is debridement to remove devitalised tissue, including slough and eschar, that can prevent the wound from healing. A unique wound treatment called HydroTherapy aims to provide an optimal healing environment. The first step of HydroTherapy involves HydroClean plus™, this dressing enables removal of devitalised tissue through autolytic debridement and absorption of wound fluid. Irrigation and cleansing provided by Ringer’s solution from the dressing further removes any necrotic tissue or eschar. Once effective wound bed preparation has been achieved a second dressing, HydroTac™, provides an ongoing hydrated wound environment that enables re-epithelialisation to occur in an unrestricted fashion. This paper presents 3 case studies of slow healing wounds treated with HydroClean plus™ which demonstrates effective wound debridement.

Community nurses often encounter chronic wounds, which continue to place significant burden on health care systems’ resources and are disabling for patients, (Posnett and Franks, 2008). The concept of wound bed preparation is not new, but remains as relevant today as when it was first introduced. Wound bed preparation is a holistic approach to wound diagnosis and treatment, it ensures patient focused outcomes and treatments, relating to the cause of the wound and the optimisation of the wound bed to promote healing (Snyder et al, 2016).

There is debate surrounding when a wound becomes classed as chronic (Sibbald et al, 2013) suggest any wound present for more than 6 weeks is considered to be chronic in nature, and as the population grows both acute and chronic wounds are becoming more frequent (Sibbald et al, 2013). Additionally, wounds can be classed as recalcitrant (non-healing) if they do not follow the expected trajectory of wound healing. Normal trajectory estimates that there should be a 30% reduction of wound surface area after only 4 weeks, if this is achieved it is projected that the wound will close within a period of 12 weeks (Margolis et al, 2004, Sibbald et al, 2013).

When healing has stalled it is vital that the community nurse has the appropriate knowledge and skills to assess the whole patient and does not simply concentrate on the wound bed (Atkin, 2014). To ensure effective patient treatment the assessment should determine the cause of the wound, identify any co-morbidities/complications that may contribute to the wound or delay wound healing, assess the status of the wound and support the development of management plans (World Union of Wound Healing Societies (WUWHS, 2008).

Devitalised tissue

In many chronic wounds there is a build-up of devitalised tissue (Nunan et al, 2014) that interferes with and delays wound healing (Snyder et al, 2016). Both slough and eschar are types of devitalised tissue that may be present in chronic wounds. The former – slough appears as moist, loose, yellow stringy dead tissue. Eschar, on the other hand has the appearance of blackish dry, thick tissue which may be leathery in consistency (Milne, 2015).

Dead tissue, slough and debris in a wound can:
■ Prevent or delay a wound’s normal healing process (Weir, 2007)
■ Mimic or hide infection, attract bacteria to the wound,
increasing the risk of infection (O’Brien, 2002)

- Prevent practitioners from assessing the extent and size of the wound, which is particularly problematic when staging pressure ulcer damage (Weir, 2007)
- Increase odour and exudate (Vowden and Vowden, 2011)

Devitalised tissue is known to provide an environment in which microorganisms can attach and form biofilms, which as a consequence results in wound infection (Percival and Suleman, 2015). Ultimately this may lead to a more serious deep tissue infection that can be life threatening (Leaper et al, 2015). In light of this, a basic tenant on the treatment of chronic (or acute) wounds is that any or all devitalised tissue must be removed allowing the wound to be prepared for healing. Therefore, removal of devitalised tissue using a debridement technique is imperative in the first steps to healing wounds and is the basis of a number of specific guidelines developed to aid the clinician to do this (Pilcher, 2016). This guidance includes the TIME management process (see Table 1), which is the acronym given to Tissue management involving wound bed preparation; control of Infection and Inflammation; Moisture imbalance; advancement of the epithelial Edge of the wound as shown in Table 1 (Dowsett, 2008).

**Wound debridement**

There are several “standard” methods by which the clinician can remove devitalised tissue including mechanical, autolytic, chemical, enzymatic and biological (larvae) debridement techniques (Mat Saad et al, 2013). Advances in technology have allowed nurses and other health care professionals access to newer debridement methods ranging from pulsed lavage debridement (hydro-surgery, water-jet) to ultrasound-assisted wound treatment (Doerler et al, 2012). However, choice of debridement technique depends on the type, amount of devitalised tissue in the wound bed, size and depth of the wound, underlying disease, possible co-morbidity, and the patient’s general condition. Combined methods of debridement may also be used to achieve better results. It is not within the scope of this article to review and critique the different methods of devitalised tissue removal, but to understand why and how this needs to be done.

**HydroTherapy**

This article highlights a unique wound treatment regimen “HydroTherapy” that consists primarily of two Hydro-
bed appeared slightly dry and as such there was no evidence of wound edge migration. HydroClean plus™ was started at this point, after only 8 days (Figure 7) there was significant progression in the condition of the wound, the sloughy tissue had started to debride, and there was evidence of new healthy granulation growth. Hydroclean plus™ was continued until the wound was completely slough free allowing skin grafting.

Discussion

Successful management strategies for treatment of chronic wounds should include wound bed preparation in terms of the “TIME” framework which encompasses tissue management, inflammation and infection control, moisture balance, and epithelial (edge) advancement as presented in – Table 1 (Dowsett, 2008). The vital first step in this process is tissue management involving wound bed preparation, ensuring that where devitalised tissue is present effective debridement cleans the wound bed thus preparing it for healing. There are a variety of different effective debridement options available however using a wound dressing that allows speedy debridement will assist in reducing time to healing and simplify the wound care process. The case studies presented here suggest that HydroClean plus™ is able to remove devitalised tissue quickly and effectively, aiding in the preparation of the wound bed for healing.

TIME framework wound healing

As previously discussed, when using the TIME framework for tissue management an essential element is to remove devitalised tissue using various methods of debridement (Pilcher, 2016). HydroTherapy aims to assist later steps in the process that involve restoration of bacterial balance (including reduction of bacterial biofilms), which relates to Infection and inflammation of this framework and through achieving a moist wound healing environment healing will be enabled. Finally, removal of the physical and biochemical barriers for migration of the epithelium from wound edges enables healing (Mat Saad et al, 2013). The effectiveness of using HydroTherapy as a basis for treatment of various chronic wounds in this case study series within the TIME framework is demonstrated in Table 1.

The mode of action of HydroClean plus™ involves cleansing, debriding and absorbing in order to stimulate granulation tissue formation. The release of Ringer’s solution from the superabsorbent polyacrylate core beads leads to the softening of necrotic tissue and fibrin coatings. At the same time, wound exudate (containing proteinaceous material and bacteria) is taken up into the body of the dressing. Further absorption of necrosis and fibrinous material softened by the cleansing action occurs. Together, these effects stimulate the quick formation of granulation tissue.

Hyper-hydration

The cases presented demonstrated that HydroTherapy may sometimes result in hyper-hydration of the skin surrounding

---

**Figure 4. Arterial ulceration 4 weeks post surgical debridement**

**Figure 5. Following 7 days of treatment with HydroClean plus**

Skin surrounding the wound, the peri-wound skin, showed some hyper-hydration but was not macerated.

**Case study 2**

The second case was a 72-year-old man with peripheral arterial disease who developed gangrene of his toes and underwent revascularisation and amputation of the 4th and 5th toes. Initially the wound progressed well but around week 4 it had started to stall, and there was evidence of increasing sloughy tissue (Figure 4). The patient was reassessed and his arterial supply remained adequate. HydroClean plus™ was commenced to allow rapid debridement and optimisation of the wound bed to facilitate granulation growth. After only 1 week there was evidence of debridement and the wound bed was shallower with healthy granulation visible (Figure 5).

**Case study 3**

A 65-year-old gentleman who suffered from an acute diabetic foot infection that required incision and drainage. The patient suffered from a neuropathy but had an intact arterial supply. Two weeks following surgery the wound started to stall, (Figure 6) with increasing amounts of sloughy tissue visible at the base of the wound, there were no signs of infection, the wound
the wound, as can be clearly seen in case 3 (Figure 8). This is a consequence of the autolytic debridement resulting from using HydroClean plus™, which aids in wound bed preparation. Initially this was some unease because it is commonly understood that excess exudate on the skin can jeopardise its integrity (Davies, 2013). However, it is important to note that although the presentation of hyper-hydration and maceration are similar they are not the same (Rippon et al., 2016). Maceration results from liquids that are damaging to the skin such as wound exudate or urine (Gray and Weir, 2007) whereas hyper-hydration results from the moist environment, in these cases created by the Ringer’s solution contained within the dressing. The most significant difference is that hyper hydration will resolve within a few minutes leaving no damage to the skin. More detail surrounding the differences is in Table 2.

These case studies suggest (Figures 3, 5 and 8) that where hyper-hydration was apparent, supported by the presentation of white and wrinkled tissue, this was transient and the skin returned to a more normal state if left without the Ringer’s solution that caused the hydrated environment, for example when the HydroClean plus™ dressing was no longer used. This does not happen if skin is macerated by wound fluid thus “excessive fluid is not per se the cause of skin damage but it is the content of the fluid that is of major importance” (Ousey et al., 2016).

### Hydration assists wound healing

Additionally, results demonstrate the benefits of hydration not only in the context of debridement but also for healing. In fact, hydration of wounds has been shown to be important for many decades (Benbow, 2008). Table 3 highlights some of the benefits of hydration in wound healing. More importantly high levels of wound tissue hydration (hyper-hydration) have proved to be effective in aiding the healing process. A number of studies have indicated that a wound that is overly hydrated may not result in tissue damage (Breuing et al., 1992; Svensjö et al., 2000; Vranckx et al., 2002; Vogt et al., 1995), and rather suggest that a wound bathed in a hyper-hydrated environment may benefit from the advantages of moist wound healing (Junker et al., 2013).

### Conclusion

The initial process of HRWD involving HydroClean plus™ was successful in effectively removing devitalised tissue and aiding progression of healing in chronic wounds. As a straightforward method of debridement we suggest nurses should consider hydrotherapy for treatment of chronic or stalled wounds.

**Table 3. Benefits of moist wound healing - taken from Ousey et al, 2016**

- Faster wound healing (Winter, 1962; Dyson et al., 1988; Beam et al., 2008)
- Promote epithelialisation rate (Winter, 1962; Eaggstein, 2001; Agren et al., 2001; Varghese et al., 1986; Rubio, 1991; Madden et al., 1989; Wigger-Alberti et al., 2009)
- Promote dermal/wound bed healing responses, e.g., cell proliferation, ECM synthesis (Svensjö et al., 2000; Dyson et al., 1992; Mosti, 2015; Korting et al., 2010; Chen et al., 1992; Leung et al., 2010; Field and Kerstein, 1994; Dowsett and Ayello, 2004; Katz et al., 1991)
- Reduces scarring (Atiyeh et al., 2003, 2004; O’Shaughnessy et al., 2009; Mustoe and Gurjala, 2011; Tandara et al., 2007; Hoeksema et al., 2013)
- Retention of growth factors at wound site (Svensjö et al., 2000; Hackl et al., 2014; Powers et al., 2013; Chen et al., 1992; Attinger et al., 2006; Vogt et al., 1995)
- Lower wound infection rates (Kannon and Garret, 1995; Hutchinson and Lawrence, 1991; Lawrence, 1994)
- Reduces pain perception (Wiechula, 2003; Metzger, 2004; Leaper et al., 2012; Coutts et al., 2008; Feldman, 1991; Nemeth et al., 1991)
